22 Abstract Ecologists increasingly appreciate the central role that urban biodiversity plays in ecosystems, however much 23 urban biodiversity is neglected, especially some very diverse groups of invertebrates. For the first time in southern 24 Europe, land snail communities are analysed in four urban habitats along a geographical gradient of three cities, using 25 quantitative methods and assessing the relative roles of local environmental conditions ("distance from sea", "distance 26 from city centre", "vegetation cover") and spatial effects by principal coordinate analysis of neighbour matrices, 27 redundancy analysis and variation partitioning. A total of 53 species was recorded, a richness similar to that of natural 28 areas. At habitat level, species richness did not show a clear increasing trend from more to less urbanized habitats, but 29 rather a homogeneous pattern. At city level, study areas hosted rather heterogeneous species assemblages and biotic 30 homogenization did not seem to have any impact; thus, only three species could be considered alien. Variation 31 partitioning showed that land snail communities were mostly structured by environmental factors, even when spatial 32 structures independent of measured environmental variables were included: "vegetation cover" and "distance from city 33 centre" were the environmental variables that explained most of the variation in species composition. The lack of strong 34 spatial structure also unexpectedly suggested that transport by humans aids dispersal of organisms with low mobility, 35 which are usually limited by spatial constraints in natural environments. These results provide ecological and 36 conservation implications for other invertebrate groups, suggesting to set priorities in management strategies that 37 include habitat conservation at local scale.

39 Introduction

40

41 Nowadays more than half the world's population lives in large urban settlements. This percentage is predicted to 42 increase to 66% by 2050 (United Nations 2014). Although it is the most common human habitat (Grimm et al. 2008), 43 the urban environment has been neglected by researchers (Maurer et al. 2000; Beninde et al. 2015; Hartop et al. 2015) 44 as unnatural and poor in biodiversity (Grimm et al. 2008; Paul and Meyer 2008; Güneralp and Seto 2013), besides 45 being subject to biotic homogenization due to the increasing number of non-native species (Lockwood 2004; McKinney 46 2006; La Sorte et al. 2007; Williams et al. 2009) and habitat fragmentation (McKinney 2002; Cadenasso et al. 2007). 47 While urbanization is certainly a major cause of biodiversity and habitat loss (Czech et al. 2000; McKinney 2006; 48 Grimm et al. 2008; Hahs et al. 2009), the influence of urban land use on biodiversity is more complex than expected 49 (McKinney 2008).

50 In recent years, the belief that cities only affect the surrounding environment negatively has been challenged. An 51 increasing body of literature has investigated urban biodiversity (Beninde et al. 2015), covering groups such as birds, 52 invertebrates, plants and even zooplankton (Mimouni et al. 2015). Surprisingly, researchers are discovering that cities 53 can protect and control vulnerable and particular ecosystems (UNEP 2005), as well as high levels of biodiversity 54 (Aronson et al. 2014) including native species (Barratt et al. 2015), sometimes showing the same dynamic interactions 55 as in nature (Baldock et al. 2015; Beninde et al. 2015). Studies have revealed the extreme ecological importance of 56 particular urban habitats for species dispersal (Angold et al. 2006). Moreover, urban green areas can have a positive 57 influence on human quality of life (Fuller et al. 2007; Mitchell and Popham 2008; Carrus et al. 2015; Taylor and 58 Hochuli 2015) in terms of recreation and public participation in scientific activities (Beumer and Martens 2015).

59 Although interest in urban ecology is increasing, not much is yet known about less charismatic invertebrates such as 60 land snails. This is surprising because according to the IUCN Red List, molluscs are the group most subject to 61 extinctions, which often go completely unnoticed (Lydeard et al. 2004; Régnier et al. 2009). The current lack of 62 scientific documentation and their low mobility make land snails susceptible to anthropogenic disturbance and habitat 63 fragmentation (Douglas 2011). Malacofauna currently includes several rare and endangered species, and constitutes 64 20% of all threatened animals and 37% of known animal extinctions since the year 1600 (Seddon 1998). Land snails are 65 numerous and diverse; they live in almost all terrestrial environments and play a key role in worldwide trophic webs 66 (Baur and Baur 1993; Douglas et al. 2013). Snails are preyed on by a wide range of animals from insects to salamanders, 67 toads, lizards, snakes, birds and mammals. Some species of fireflies (i.e. Pyrocoelia pectoralis, Cratomorphus spp.) 68 feed mainly on land snails (Viviani 2001; Wang et al. 2007). Many birds require a huge quantity of calcium carbonate 69 for the formation of eggshells, relying on land snails for Ca supplementation (Mänd et al. 2000). Their low mobility 70 makes snails, who also have good bioaccumulation capacity (Pauget et al. 2013), perfect bioindicators of environmental 71 quality (Cuttelod et al. 2011; Rota et al. 2016).

72 Studies on urban ecology are often descriptive checklists of traditional biodiversity components, such as richness 73 and diversity measures. Since interactions between communities and their physical environment, and between 74 organisms, occur at precise spatial and temporal scales (Borcard et al. 2004), discovering spatial structures at each scale 75 and the processes involved in their creation is important for understanding the ecological patterns of natural 76 communities (Borcard et al. 2004). In ecology, space has a key role in shaping the distribution of species assemblages, 77 even if it is often neglected. Spatial heterogeneity is often driven by a wide range of factors that interact with each other 78 in different ways (Borcard et al. 1992). The traditional niche-based model assumes that the local environment itself 79 controls the spatial structure of species assemblages: in other words the interaction between a species and its physical

environment may mould its distribution through adaptation to and interaction with different habitat features (Borcard et
al. 2004). According to this model, it is the environment itself, through resource types and habitat conditions, that
determines how similar/dissimilar communities are, irrespective of spatial proximity or distance between assemblages
(Caruso et al. 2012). Sometimes spatial structures may be generated by species assemblages themselves and can persist
despite environmental changes (neutral model) (Hubbell 2001). In this case the space effect is described directly by
community dynamics through dispersal limitations, demographic stochasticity or competitive/predatory processes
without any environmental influence (Legendre et al. 2009).

87 Advanced and nowadays well established multivariate techniques such as principal coordinate analysis of neighbour 88 matrices (PCNM) and variation partitioning (ter Braak 1986; Borcard et al. 1992; Legendre and Legendre 1998; Borcard 89 and Legendre 2002; Borcard et al. 2004) have recently made it possible to disentangle and quantify the relative and pure 90 effects of environment and space in shaping variations in community composition (β diversity), as well as the fraction 91 of species variation explained by space and environment together. These techniques provided a useful tool for 92 quantifying the amount of variation uniquely attributable to measured environmental factors, separating it from spatial 93 structures potentially created by unmeasured environmental factors but also population and dispersal dynamics 94 independent of environmental factors (e.g Legendre et al. 2009).

95 In southern Europe, there has been a complete lack of any quantitative and spatially explicit research into any aspect 96 of urban land snail biodiversity, whereas in central Europe Horsák et al. (2009) and Lososová et al. (2011) have been 97 the only authors to compare plant and land snail diversity in different urban habitats across several cities, using a 98 standardized sampling protocol. Chytrý et al. (2012) subsequently highlighted the importance not only of the 99 environmental but also of the space effect in shaping urban community structure across groups of different sizes and 100 with different dispersal abilities (i.e. subaerial cyanobacteria and algae, vascular plants, land snails, grass, and animal-101 dispersed or wind-dispersed trees and shrubs) in central European cities. Thus we have a major gap in scientific 102 knowledge, since the Mediterranean is one of the world's richest areas in terms of species diversity, but also one of the 103 most threatened, mainly by human impact, especially habitat loss and degradation (Cuttelod et al. 2008). In this 104 geographical context, the extremely complex biogeographical framework of Italy makes it a huge source of 105 biodiversity: with regard to molluscs, the second in Europe, ranking just after Greece in terms of species and subspecies 106 richness (Cuttelod et al. 2011).

107 Here for the first time, the spatial variation component of urban land snail communities is studied in different 108 habitats along a geographical gradient of three cities in Tuscany (Italy). The aims of the study were: 1) to analyse and 109 compare land snail biodiversity in terms of richness and potential differences in species composition (alpha α , beta β 110 and gamma γ diversity) in four different human habitats along a gradient of three cities in central Italy; 2) to evaluate 111 the presence of species of European Conservation Concern (ECC) and the impact of alien species, if any; 3) to detect 112 factors affecting community structure by partitioning the pure effect of "environment" (measured environmental factors) 113 from that of "space" (unmeasured environmental variation, biotic interactions that structure population spatially even 114 within an environmentally homogeneous habitat and also dispersal limitations), as well as the combined effect, on the 115 distribution of urban land snail communities by means of multivariate variation partitioning. 116

117

118 Materials and methods

- 119
- 120 Study area

121

We investigated three central Italian cities along a geographical transect about 100 km long, extending from the Tyrrhenian coast to the Apennine mountain chain (Fig. 1). The cities differ for example in altitude, population and foundation date, but all have old city walls.

Grosseto (altitude 10 m, population 82,284, area 474 km²) is located in southwestern Tuscany, 10 km from the Tyrrhenian coast. Situated in the alluvial plain of the Ombrone river, the largest plain in southern Tuscany, Grosseto was founded in the High Middle Ages. Its Medicean walls were begun in 1574, replacing those from the 12th-14th centuries. Climate is Mediterranean with mild wet winters and hot dry summers.

Siena (altitude 322 m, population 52,774, area 118 km²) is located in central Tuscany and is the highest of the three cities and the one with the smallest population. Founded in Roman times, it has well preserved green areas within its perimeter. The historical centre of Siena, a UNESCO World Heritage Site, is surrounded by medieval walls, which include the Medici fort (1561-1563). Climate is sub Mediterranean with precipitation sufficiently distributed throughout the year, so there is no real dry season.

Arezzo (altitude 296 m, population 99,232, area 386 km²) is further east, near the Apennines. It is the oldest of the three, believed to have been one of twelve major Etruscan cities. Climate is continental due to its location straddling the Arno and Chiana valleys at the foot of the Apennines. In the high part of the town the Medicean walls enclose the cathedral, town hall and Medici Fortress.

138

139 Sampling design and data collection

140

141 Sampling design included four urban habitat types over a gradient of human impact from heavily affected and disturbed 142 sites to quite well preserved naturalized habitats (Lososová et al. 2011). Google Earth and city maps were used to 143 choose two spatially independent sites for each habitat type in the three areas, making a total of 24 sites. Habitat types 144 were chosen according to the standardized protocol of Lososová et al. (2011) with modifications: 1. WALLS: historical 145 walls of the city centre; 2. PARK: city parks and public gardens with old deciduous trees (tree cover 10-50%) and 146 frequently mown lawns; 3. E-SUC: early successional sites, strongly disturbed in the last 1–3 years, with a prevalence 147 of bare ground and sparse vegetation cover, usually in or around construction and industrial sites; 4. WOOD: quite well 148 preserved wooded patches, with well-structured vegetation (old and young trees, especially holm oak with scattered 149 shrubs).

A qualitative visual search (presence/absence) was conducted for a standard time of 2 h at each site. The timeconstrained sampling strategy made it possible to maximize species numbers by including a huge number of heterogeneous microhabitats and environmental conditions. It also avoided logistic problems related to sampling activity on vertical surfaces (city walls), where a common standard-sized plot can be hard to arrange.

In each site, 5 litres of debris and leaf litter was also collected to detect small and very small species (Cameron and
Pokryszko 2005). Despite the huge investment in effort and time, this "volume method" combined with visual search
produces more information on small species (Menez 2007; Benocci et al. 2015).

The litter was sieved with a 10 mm mesh, then dried and sieved again with meshes of decreasing size down to 0.5
mm. Specimens were determined at species rank and recorded in a database. The nomenclature follows Manganelli et al.
(1995) and subsequent updates. Voucher specimens were deposited in Manganelli collection, Dipartimento di Scienze
Fisiche, della Terra e dell'Ambiente, Università di Siena (Italy).

- 162 Explanatory variables
- 163

Two groups of explanatory variables (environmental and spatial) were calculated for each site and used to model land snail species richness and composition. The environmental properties of each site were quantified by three variables: 1) distance from city centre ("*Dist_center*") measured as linear distance from the city cathedral to the sampling site (Horsák et al. 2009); 2) distance from sea ("*Dist_sea*") assessed as minimum linear distance from the site to the nearest point on the coastline; 3) vegetation cover ("*Tree_cover*"), ranging from 0 to 100% of total area of sampling site. Spatial variables were XY geographical coordinates and all the spatial structures at different scales detected by PCNM.

170

171 Statistical analysis

172

173 Observed and estimated species richness

174

175 α , β and γ diversity were used to assess richness and diversity patterns at habitat and city level. α diversity was defined 176 as species richness in each of the 24 sites and γ diversity as species richness in each urban habitat or city. β diversity, 177 concerning species composition turnover within and between habitats and cities, was examined by the Simpson 178 dissimilarity index (β sim; Baselga et al. 2007), which only considers dissimilarity due to spatial turnover, irrespective 179 of species richness (Baselga 2010). Analysis of Variance (ANOVA) and Bonferroni p-value adjustment for multiple 180 comparisons were used to test for statistically significant differences. The Chao2 richness estimator and its standard 181 error Chao.se (Chao 1987) were also used to estimate the minimum asymptote of species richness for habitats and cities 182 in order to detect the number of unseen or undetected species in relation to observed species richness and sampling 183 efficiency.

184

185 Environmental and spatial effects on land snail assemblages: PCNM and Variation Partitioning

186

187 To evaluate the effects of environment and space on species composition, principal coordinate analysis of neighbour 188 matrices (PCNM, Borcard et al. 2004) was used to detect spatial structure in the data. Compared to traditional 189 multivariate trend-surface analysis, PCNM detects, decomposes and models any type of hidden spatial structure in the 190 data, within the limits of sampling design (Borcard and Legendre 2002). It makes it possible to select the best linear 191 combination of eigenvectors, maximizing correlation with the data and minimizing the number of vectors (Dray et al. 192 2006). We first computed a matrix of Euclidean distances among the 24 sites using the latitudes and longitudes of 193 sampling sites. Before running PCNM, the data was detrended by regressing all variables against the geographical 194 coordinates (X-Y), retaining residuals. The Euclidean distances were then truncated: PCNM is based on the assumption 195 that the only meaningful spatial signals for plots are those circumscribed by neighbourhood sites (Dray et al. 2006). The 196 truncation distance, which defines neighbourhood thresholds, is considered the maximum distance connecting all plots 197 based on a minimum spanning tree criterion (Rangel et al. 2006). The give.thresh function in the spacemakerR package 198 was used.

PCNM was performed on the modified (i.e. truncated) distance matrix to extract eigenvectors (PCNM variables) to use as new spatial explanatory variables. Since PCNM are orthogonal, each PCNM variable represents an independent spatial gradient. The higher the eigenvalue of a PCNM variable, the broader the spatial scale represented, while PCNM variables with low eigenvalues only explain small fractions of the total spatial structure and are related to finer spatial 203 gradients (Duarte et al. 2012). The model selection procedure was based on multivariate extension of the AIC criterion 204 using the ortho.AIC function in the SpacemakeR package. Six PCNM vectors obtained from the X-Y coordinates of 205 each sampling site were then entered as explanatory variables for Redundancy Analysis (RDA) to account for the space 206 effect on the urban land snail matrix. To reveal the urban gradient effect after removing the effect of space (i.e. pure 207 spatial patterns that cannot be related to any measured variable + unmeasured spatially structured environmental 208 variation), we computed the relative contribution of the three environmental variables (distance from city centre, 209 distance from sea, % vegetation cover) by partial RDA (pRDA) that excluded spatial influence from the community 210 matrix.

Variation partitioning was later conducted to detect the fractions of total variance explained exclusively by the environmental predictors [a], by environment and space [b], exclusively by spatial variables [c] and finally by residual variation (Borcard et al. 1992; Peres-Neto et al. 2006), which can be ascribed to internal biological variation, survey error, or variables not included in the analysis (Legendre and Legendre 1998). Quantification of the variance components was based on the *varpart* function of the Vegan R package (Oksanen et al. 2016).

All multivariate statistical analysis based on Hellinger-transformed land snail presence/absence data was performed
 with RStudio version 0.99.473 (RStudio Team 2015).

- 218
- 219

220 Results

221

223

222 Observed and estimated species richness

Total land snail richness was 53 species (Table 1). Communities were dominated by *Cornu aspersum* and *Xerotricha conspurcata* present in 19 and 18 out of 24 sites, respectively, while rare species such as *Howenwartiana howenwartii*,
 Marmorana serpentina, Cepaea nemoralis and *Vitrea etrusca* occurred in 2 or 3 out of 24 sites. Some species are
 ranked as LC (Least Concern) in the IUCN Red List, while only three are alien (the Australasian *Paralaoma servilis,* the Sardo-Corsican *Marmorana serpentina* and the Mediterranean *Deroceras invadens*).

229 Numbers of land snail species found in sites ranged from 5 to 29 with a mean of 14 (Lososová et al. 2011: 0-21, 230 mean 7.5). The lowest mean number of land snail species per site (α diversity) was found in early successional sites (E-231 SUC) and old city walls (WALLS) (9 and 13, respectively) while the highest mean α diversity was in wooded sites 232 (WOOD) and urban gardens and parks (PARK) (17 and 16, respectively). The total number of species found in each 233 habitat type (γ diversity) was lowest in early successional sites (E-SUC: 30) and increased in old city walls (WALLS: 234 31), reaching its highest values in wooded suburban areas (WOOD: 37) and parks (PARK: 38) (Fig. 2a). Across 235 habitats, γ diversity was correlated with mean α diversity (r=0.94, p=0.05). One-way ANOVA (df 3; F-value 2.793; P-236 value 0.067) revealed no significant difference among habitat types. β diversity was highest in E-SUC, lowest in all the 237 other habitats. This agrees with the findings of Lososová et al. (2011) (Fig. 3a). One-way ANOVA (df 3; F-value 12.25; 238 P-value 2.87e-06) and Bonferroni p-value adjustment for multiple comparisons showed that E-SUC significantly 239 differed with respect to all the other habitats in β diversity values (E-SUC-PARK p=9.5e-05; E-SUC-WALLS p=3.7e-240 05; E-SUC-WOOD p=2.5e-05). Pairwise β diversity values between habitat types were: WALLS-PARK 0.16; 241 WALLS-E-SUC 0.37; WALLS-WOOD 0.32; PARK-E-SUC 0.20; PARK-WOOD 0.19; E-SUC-WOOD 0.17.

242 The lowest mean α diversity in the cities was recorded in Grosseto (GR) and Arezzo (AR) (11 in both cases) while 243 the highest was recorded in Siena (SI) (19). The total number of species found in each city (γ diversity) was lowest in Grosseto (29), higher in Arezzo (35) and highest in Siena (44) (Fig. 2b). Across cities, γ diversity was not correlated with mean α diversity (r=0.84, p>0.05). After one-way ANOVA (df 2; F-value 6.439; P-value 0.007) and Bonferroni correction for multiple comparisons, the SI-GR and SI-AR pairs proved to be significantly different in α diversity (SI-GR p=0.014; SI-AR p=0.018). Arezzo showed the highest internal β diversity, while Grosseto and Siena showed similar values (Fig. 3b). After one-way ANOVA (df 2; F-value 9.739; P-value 0.0002) and Bonferroni p-value adjustment, the AR-GR and AR-SI pairs resulted to be significantly different in β diversity values (AR-GR p=0.001; AR-SI p=0.001). Pairwise β diversity values between cities were: SI-GR 0.17; SI-AR 0.14; AR-GR 0.38.

The minimum estimated *Chao2* richness and its standard error *Chao.se* differed among habitat types and cities (Fig.
4a,b). However, a few species are missing: more or less all species were detected with a reasonable degree of certainty through sampling effort.

254

256

255 Environmental and spatial effects on land snail assemblages: PCNM and Variation Partitioning

257 Total species matrix variation (Table 2) can be portioned in four parts: (a) pure effects of space, (b) combined variation 258 i.e. spatially structured environmental variation, (c) pure effects of environment, (d) residual variation (Borcard et al. 259 1992). In our data matrix, the total contribution of spatial structures (a + b) accounted for 16% of community structure 260 whereas the variation attributed solely to pure spatial patterns, i.e. patterns that cannot be related to any measured 261 environmental variable, was 13% (a). Environmental factors (c + b) are invoked to explain a higher portion of species 262 matrix variation (22%) than explained by spatial structures. Furthermore, almost all of this rather high variation (c) 263 (19%) is ascribed to the pure effect of environment, i.e. species-environment relationship associated with local 264 environment, irrespective of space. The percentage of residual variation (d) was large: more than half the total variation 265 remained unexplained, while only 3% of the explained variation was shared (b) between the two factors. All the 266 variation components had a significant effect (p<0.05). Redundancy analysis (Fig. 5) detected significant effect in 267 shaping urban land snail composition for two out of three local environmental variables, namely "distance from the city 268 centre" and "vegetation cover". Papillifera papillaris was clearly negatively associated with Dist_center and was the 269 most characteristic species of WALLS assemblages followed by Mediterranea hydatina, which was also negatively 270 associated with Tree_cover; Hohenwartiana hohenwartii was most linked to E-SUC habitat type, Monacha 271 parumcincta was clearly positively associated with Dist_center and Tree_cover, proving the most characteristic species 272 of WOOD assemblages, while Deroceras invades and Cernuella virgata were associated with PARK habitat type.

273 274

275 Discussion

276

277 This study is the first to consider the influence of environment and spatial factors on urban land snail communities in 278 southern Europe, and the insights it provides are unexpected. In terms of land snail total species richness, we recovered 279 53 species over our 100 km transect, compared to the 87 species recorded over a much larger transect (>1200 km) in 280 central Europe by Chytrý et al. (2012) and the 54 forest entities found in three well preserved forest areas of Tuscany 281 (Benocci et al. 2015). These numbers suggest that urban environments may actually offer a range of different habitat 282 and environmental conditions to land snails, thereby creating a sort of heterogeneous melting pot of unlimited 283 ecological situations. Perhaps, the many species found in the assemblage posses a wide variety of ecological 284 requirements, which even in urban environments allow them to find optimal conditions to adapt, flourish and spread,

just as happens in naturalized areas. The various results collected in this study support this general interpretation and wediscuss these results below in terms of our three main aims.

287

288 α , β and γ diversity

289

290 Concerning habitat γ diversity, we did not find a clear decreasing trend from more (WALLS and PARK) to less 291 urbanized habitats (E-SUC and WOOD), but rather a homogeneous pattern with just a dip in proximity to early 292 successional sites. These open sub-urban habitats are typically in city peripheries; many are highly disturbed, often 293 close to busy roads or industrial settlements, and function as ecological corridors (or barriers?) to the open countryside 294 or woods. On the other hand, city parks, public gardens and wooded patches proved to be genuine islands of 295 biodiversity in the urban matrix, showing the highest values of both α and γ diversity. This finding agrees with other 296 research from which it emerged that parks were the most diverse urban habitat for several groups of organisms 297 (Lososová et al. 2011). Pairwise species composition differences between habitats showed major β diversity values, the 298 highest difference being between WALLS and E-SUC habitats: PARK and WOOD shared a common more or less 299 forested matrix, whereas WALLS and E-SUC showed the strongest differences in terms of ecological conditions and 300 environmental heterogeneity. At city level, Siena had the richest α and γ diversity: it is the greenest of the three cities, 301 characterized by many well preserved wooded and green patches inside the urban core, also relatively less impacted by 302 vehicular traffic and the effects of urbanization. These results overall imply the great diversity of conditions in urban 303 environments, which is reflected by diversity patterns in the land snail assemblage.

304

305 Conservation status

306

307 The checklist did not include species in danger of extinction or threatened; xenodiversity was apparently very low and 308 only three species (5.7% of the total) were true aliens: Paralaoma servilis is a worldwide litter- and humus-dwelling 309 invasive species, probably of Australasian origin (Manganelli et al. 2015); Deroceras invadens, probably of central 310 Mediterranean origin, is an invasive species worldwide (Reise et al. 2011) and Marmorana serpentina, first reported 311 from the city of Grosseto by the present research, occurs in Sardinia and Corsica and has been introduced into certain 312 Tuscan cities (Livorno, Pisa, Siena) (Fiorentino et al. 2009). As regards the remaining species, at least two (Lehmannia 313 melitensis, Papillifera papillaris) may also have been introduced by anthropochory. They are nearly always found in 314 habitats at the edge of urban areas or used by man at some time in the past. Finally, vast open and built-up areas have 315 probably facilitated colonization by potentially indigenous but originally less widespread synanthropic species, such as 316 the slug Limacus flavus and land snails Xerotricha conspurcata, Eobania vermiculata and Cornu aspersum (Manganelli 317 et al. 2015). Biotic homogenization therefore does not seem to have had remarkable ecological impact: the small 318 Tuscan cities still maintain considerable β diversity, both within and between study areas, despite the restricted 319 geographical distance gradient. Thus they differ from other cosmopolitan urban areas in Europe where the introduction 320 of invasive species, together with human-mediated biotic interchange, resulted in widespread floristic and faunistic 321 homogenization (La Sorte et al. 2007; Ferenc et al. 2014).

322

323 Factors affecting community structure

325 Our attempt to discover the processes underlying land snail community structure by partitioning the pure effects of 326 "environment" and that of unmeasured factors (dispersal, biotic interactions, unmeasured environmental variables) that 327 create spatial structure (called "space"), provided the most interesting findings. Environment and space can be equally 328 important in shaping communities but their function should always be considered in relation to the dispersal capacity of 329 the group in question (Heino 2013). The relative role of deterministic and stochastic aspects driving ecological 330 metacommunities has been examined in different organisms in natural environments (e.g. oribatid mites, Caruso et al. 331 2012; oribatid mites and collembola, Ingimarsdóttir et al. 2012; microbial communities, Caruso et al. 2011; several 332 groups of aquatic organisms, Padial et al. 2014, Rádková et al. 2014, Zhai et al. 2015) but few studies have concerned 333 urban areas (spiders, bees and birds, Sattler et al. 2010; subaerial cyanobacteria and algae, vascular plants and land 334 snails, Chytrý et al. 2012). According to general belief, high dispersers should be less influenced by spatial effects since 335 they move more readily to suitable habitat than low dispersers and species are consequently sorted according to their 336 ecological requirements (Martiny et al. 2006; Heino 2013). Conversely, weak dispersers are expected to show 337 significant spatial structuring as a direct consequence of their low mobility while their distribution is often due to 338 stochastic processes mediated by limited dispersal (Bell 2000; Hubbell 2001). Paradoxically, although land snails are 339 widely recognised as having low mobility (Baur and Baur 1993), they proved to be most significantly shaped by pure 340 and spatially independent environmental processes, which often turn out to be irrelevant since the environment is 341 usually spatially structured by various ecological processes (Legendre and Fortin 1989). In other words, after removing 342 the effect of space (i.e. pure spatial patterns that cannot be related to any measured variables + unmeasured spatially 343 structured environmental variation), urban gradient turned out to be the main factor modelling land snail community 344 structure.

345 Some exceptions to the rule were also found by Hájek et al. (2011), who described much stronger environmental 346 than spatial structure in bryophytes but not in high dispersers such as diatoms in Western Carpathian fens, and similarly 347 Astorga et al. (2012) confirmed a preponderant influence of niche-related factors rather than spatially limited dispersal 348 in bryophytes and macroinvertebrates in Finnish streams. Sattler et al. (2010) first took urban environments seriously 349 into account, observing higher environmental influence and weak spatial structure for spiders over a gradient of three 350 Swiss cities. According to Sattler et al. (2010), this combination with traditionally limited dispersers may be a feature 351 typical of urban areas, where high disturbance affecting the heterogeneous mosaic of urban habitat could inhibit 352 establishment of well-defined spatial structures, selecting only the species able to adapt and coexist with human 353 activities. Recent studies on land snail dispersal confirmed the possibility of long distance passive dispersal (Ozgo et al. 354 2016) so that human-mediated transport in urban environments may be the most reasonable explanation for the high 355 pure environmental constraint detected in urban land snail data: molluscs can be passively dispersed, but only if 356 environmental conditions are suitable do they establish and develop well defined assemblages. Diverse microhabitat 357 conditions and small-scale habitat structures are in fact necessary conditions for mollusc diversification, assuming a 358 suitable geological substratum (Cuttelod et al. 2011). The pure environmental contribution therefore suggests selection 359 of species well adapted to man-made environments, while other species show random distributions, probably as a 360 consequence of occasional dispersal events.

The hypothesis of stronger environmental effect was also confirmed by RDA analysis that showed four well structured and differentiated species assemblages at habitat level, as demonstrated by 95% confidence ellipses (Fig. 5).

363 "Distance from the city centre" and "Vegetation cover" proved to be the environmental variables most significantly
364 involved in explaining variation in species composition. With the exception of parks and gardens within the city limits,
365 which can be considered genuine islands of richness and biodiversity inside the urban core (Dedov and Penev 2004),

366 the greater the distance from the urban centre, the higher the vegetation density. It is well known that forest cover 367 provides shelter for land snails under unfavourable conditions (Dedov and Penev 2004). This has strong implications 368 for species richness since the richest urban habitats are generally those with the highest tree and vegetation cover values 369 (PARK and WOOD in our study). At the same time different forest cover values work as ecological filters, selecting 370 species that depend on different environmental conditions. It is true that poor assemblages with few species are usually 371 more frequent close to city centres, due to the reduced frequency of natural habitat (Horsák et al. 2009), but although 372 poor in terms of richness, these completely anthropogenic assemblages often consist of surprisingly unique entities: 373 WALLS harbour extremely specialist species (e.g. Marmorana serpentina, Papillifera papillaris, Papillifera solida), 374 that shelter in rock clefts and cracks, instead of in litter and vegetation. Furthermore, subterranean species living in the 375 ground behind walls, such as Mediterranean hydatina, which proved to be typical species in WALLS assemblages, can 376 be included in this habitat.

The response of local land snail assemblages to urbanisation cannot be described as a gradual and linear decline in species richness with proximity to the city centre (Horsák et al. 2009), but rather as a clear change in species composition through selection/adaptation to different ecological conditions, presumably after passive human-mediated dispersal.

381 This significant environmental effect, reflecting niche processes as well as environmental filtering, is an interesting 382 result since a strong spatially independent environmental constraint has never previously been detected for organisms 383 limited by low dispersal within the urban matrix. This finding suggests the effect of human-mediated transport in 384 enhancing the dispersal capacity of organisms normally considered to have low mobility. However, the snails would not 385 become established in the absence of suitable microhabitat conditions. In particular, two urban environmental variables 386 were the main constraints shaping urban land snail communities, namely vegetation cover and distance from the city 387 centre. The detection of a pure spatially independent environmental effect has important conservation implications 388 which go beyond the analysis of a single taxonomic group: irrespective of study area position, sampling in different 389 cities would presumably show similar species assemblages explained by exactly the same dataset of environmental 390 variables.

391 392

393

Conclusion

394

In conclusion, urban environments can show high land snail richness, like natural areas; species richness does not show a clear inverse trend in relation to urbanization of habitats, but rather a homogeneous pattern. While parks prove to be real islands of biodiversity inside the urban patchwork in terms of species composition, only urban environments such as old city walls provide ideal environments for many specialist species with particular ecological requirements (i.e. carbonate rocks, shaded walls rich in calcium and moist refuges).

Although the transect we studied was only 100 km, the gradient explained an higher amount of variation to that obtained by Lososová et al. (2011) and Chytrý et al. (2012) with transects of more than 1200 km in central Europe. In addition to demonstrate the wealth of diversity patterns offered by the Mediterranean area and especially the Italian peninsula, this finding furnishes a proof of the necessity of combining traditional visual search with debris and leaf litter collection. Indeed, leaf litter collections allowed quantification of small and micro-snails.

405 City study areas host rather heterogeneous species assemblages where biotic homogenization seems very low: only
406 three out of 53 species were true alien species (*Paralaoma servilis, Marmorana serpentina* and *Deroceras invadens*).

407 After detecting and removing the influence of spatial structures, the effect of urban gradient turned out to be the 408 principal component structuring urban land snail assemblages. In particular, "Distance from the city centre" and 409 "Vegetation cover" were the environmental variables that explained most of the variation in species composition. This 410 finding shows the importance of environmental factors, possibly because of a combination of niche and environmental 411 filtering at local level for organisms with low mobility, which are usually structured by spatial constraints. It also 412 suggests new urban scenarios with major ecological and conservation implications for other invertebrate groups: inside 413 this complex urban matrix, even intensively managed habitats could support particular assemblages as results of unique 414 interactions between species and environment at local scale. This provides guidance for managers to set priorities in 415 management strategies that include habitat conservation at local scale.
