Summary

We report the results of imaging and cytogenetic studies in a case of triorchidism in a 54 years old male without any associated anomaly.

A scrotal ultrasonography revealed the presence of two testes within the left hemiscrotum with complete septation and echotexture and vascular flow pattern similar to the vascular flow of the normal right testis. There was no focal abnormal echogenicity suggesting malignancy. Scrotal MRI confirmed two soft-tissue structures in the left hemiscrotum with normal signal intensity at T1w and T2w images. Both testes had a tunica albuginea with low-signal intensity. Cytogenetic analysis resulted in normal male karyotype 46XY. Array-CGH analysis detected the presence of two interstitial rearrangements: a ~120 Kb deletion of chromosome 1 and a ~140 Kb deletion of chromosome 16. Currently there are little details on the functions of both genes.

KEY WORDS: Polycorchidism; Ultrasonography; MRI; Cytogenetic evaluation.

INTRODUCTION

Polycorchidism is a rare genital anomaly defined by the presence of supernumerary testes usually within the scrotum. To date there have been almost 200 cases reported in the literature (1, 2). The most common presentation of polycorchidism is triorchidism with the supernumerary testis being confined to the left side. The exact mechanism for occurrence of polycorchidism is still unknown. Several theories have been proposed, including peritoneal folding, segmentation of the primitive gonads, longitudinal or transverse division of the genital ridge. No single theory can explain all types of polycorchidism since some involve testicular tissue only and others involve complete duplication of the testis, epididymis and vas deferens (3, 4). Most cases of polycorchidism are found incidentally in association with undescended testis, hydrocele, hernia or torsion. It is also reported as increased risk of testicular malignancy.

CASE REPORT

A 54 years old man presented to our outpatients Department with complaints of erectile dysfunction. His past medical history revealed diabetes type 1 since the age of 28 years and 10-year history of a left-sided scrotal swelling associated with some discomfort. He was married and fathered two daughters.

Abdominal examination was normal with no palpable mass or groin herniae. Scrotal examination revealed a normal right testis and scrotal content, but on the left side there were two similar size lumps. Laboratory studies, including hormonal and oncological markers, were within normal limits.

A scrotal ultrasonography revealed the presence of 2 testes within the left hemiscrotum with complete septation and echotexture and vascular flow pattern similar to the vascular flow of the normal right testis. There was no focal abnormal echogenicity suggesting malignancy (Figure 1). Scrotal MRI confirmed 2 soft-tissue structures in the left hemiscrotum with normal signal intensity at T1w and T2w images. Both testes had a tunica albuginea with low-signal intensity (Figure 2).

Chromosomal preparations for the karyotype analysis were obtained according to standard techniques. Cytogenetic analysis at a resolution of 400 bands resulted in normal male karyotype 46XY.

Patient DNA was analysed by Array-CGH analysis using a commercially available oligonucleotide microarrays containing about ~4.000 60-mer probes (Human Genome CGH Microarray 44B Kit, Agilent Technologies, Santa Clara, California) according to the manufacturer’s instructions. Array-CGH analysis detected the presence of two interstitial rearrangements: a ~120 Kb deletion of chromosome 1 (arr1q31.1(79,356,819-79,476,571)x1) and a ~140 Kb deletion of chromosome 16 (arr 16q22.1(70,052,164-70,193,889)x1). Parents were not available for testing. The microdeletion of chromosome 1 includes the ELTD1 (latsrophilin and seven transmembrane domain containing1) gene, while the microdeletion of chromosome 16 includes the PDPR (Pyruvate Dehydrogenase Phosphatase Regulatory Subunit) gene. Currently there are little details on the functions of both genes. The protein encoded by ELTD1 could be involved in cardiac development. The
protein encoded by PDPR is a regulatory subunit of human mitochondrial pyruvate dehydrogenase phosphatase. It decreases the sensitivity of PDPI to magnesium ions, and this inhibition is reversed by the polyamine spermine. Both these proteins are expressed also in tests.

A diagnosis of triorchidism was made and the patient was placed in sonographic follow up.

Figures are reported in Supplementary materials posted on www.aiua.it

**DISCUSSION**

Polycorchidism is a rare congenital anomaly defined by the presence of more than two histologically proven testes. The commonest variant is triorchidism, the supernumerary testis being commonly reported on the left side which often appears as a painless scrotal mass or may be found as an incidental finding on sonography. Ultrasonography is diagnostic, MRI plays a confirmatory role and may provide additional information in conditions that may complicate polycorchidism, such as torsion, cryptorchidism and neoplasia (4-6).

Most patients with polycorchidism have a normal 46XY karyotype and adult patients have normal secondary sexual characteristics. Because polycorchidism is rare and poorly described, genetic studies are lacking. Chromosomal abnormality such deletion of the long arm of chromosome 21 has been reported in a severe malformed male newborn (7).

The current knowledge does not allow to attribute a causative role to the aploinsufficiency of two genes in determining the phenotype of our patient. Additional Array-CGH analysis in patients with supernumerary testes are required to increase data and to define the role of these genes in the pathogenesis of polycorchidism. Management of polycorchidism has been the subject of much debate (8). The incidence of testicular malignancy in polycorchidism is between 5.7-7% and was found only in a non-scrotal (abdominal or inguinal) supernumerary testis. With recent improvements in imaging techniques such as ultrasound and MRI scans, most cases of polycorchidism can be diagnosed and followed up accurately without any need for surgical exploration or histological examination. Conservative treatment with sonographic follow-up is the choice of treatment in uncomplicated cases (9).
